Conversion of carbon dioxide (CO₂) to carbon monoxide (CO) and other value-added carbon products is an important challenge for clean energy research. Here we report modularization of covalent organic frameworks (CoF), in which the building units are cobalt porphyrin catalysts linked by organic struts through imine bonds, to prepare a catalytic material for aqueous electrochemical reduction of CO₂ to CO. The catalysts exhibit high Faradaic efficiency (90%) and turnover numbers (up to 290,000, with initial turnover frequency of 9400 hour⁻¹) at pH 7 with an overpotential of ~0.55 volts, equivalent to a 26-fold improvement in activity compared with the molecular cobalt complex, with no degradation over 24 hours. X-ray absorption data reveal the influence of the CoF environment on the electronic structure of the catalytic cobalt centers.

The COF could be tuned electronically and sterically (26) while providing ready access for the substrate (27–32) (Fig. 1). Moreover, these crystalline porous frameworks offer the possibility to perform multivariate synthesis, in which topologically identical and yet functionally modified building blocks can be introduced into the structure. This approach can potentially give rise to materials with emergent properties that are greater than the sum of the individual molecular parts, because one can predictably prepare a topologically ordered framework that introduces heterogeneity in the number and ratio of functionalities by the choice of building blocks (33). Here we show that incorporation of catalytic cobalt porphyrin (34) units into CoFs, along with multivariate synthesis of frameworks bearing catalytic cobalt and structural copper units, gives highly active, stable, and selective catalysts for electrochemical reduction of carbon dioxide to carbon monoxide in water. A member of the CoF series that we studied exhibits a 26-fold increase in activity compared with the parent molecular precursor and, in many respects, outperforms state-of-the-art molecular and solid-state catalysts, with broad opportunities for further improvement through modular synthesis using appropriate combinations of building units. X-ray absorption measurements reveal that the CoF framework can directly influence the electronic structure of the catalytic cobalt centers, in a manner akin to redox noninnocent ligand behavior observed in molecular systems (35), thereby contributing to the observed gains in reaction selectivity and activity beyond the steric effects of surface area and site isolation.

We focused our initial electrocatalysis studies on CoFs, as we sought to exploit the charge-carrier mobility of these materials derived from π conjugation and π–π stacking (22, 36–38), as well as the stability from reticular assembly with strong covalent bonds. We synthesized a model framework (COF-366-Co) by the imine condensation of 5,10,15,20-tetrakis(4-aminophenyl)porphinato cobalt (CoTPA) with 1,4-benzenedicarboxaldehyde (BDA) (Fig. 1). The porous COF material was evacuated by activation with supercritical carbon dioxide and heated to 100°C for 18 hours. The retention of cobalt in the coordinating porphyrin units within the framework was confirmed by elemental analysis (supplementary materials section S1), thermogravimetric analysis (fig. S1), and
solid-state ultraviolet-visible (UV-Vis) spectroscopy (fig. S3). The formation of the imine linkages in the COF was confirmed by attenuated total reflectance–Fourier transform infrared spectroscopy, which showed the characteristic imine stretching vibration band at 1621 cm⁻¹, as well as the absence of the aldehyde stretching vibration band at 1684 cm⁻¹ (fig. S10). The morphologies of the activated COF samples were examined by scanning electron microscopy (SEM), which showed aggregation of only one kind of crystal-like of rectangular rod-shaped morphology (~50 nm in length) (Fig. 2A). Powder x-ray diffraction (PXRD) patterns (Fig. 2B) showed intense peaks in the expected low-angle range, with no residual peaks characteristic of the starting materials. To elucidate the constitution of the framework, we used Materials Studio 7.0 to build a structural model (Fig. 1) in an orthorhombic Cnmm space group to allow the lattice distortion from regular square nets. Pawley refinements of the PXRD patterns were carried out for full profile fitting against the proposed models, resulting in a good agreement factor (weighted-profile R factor R_wp = 2.59% and unweighted-profile R factor R_p = 1.38% after convergence) and reasonable profile differences. These refinements revealed one-dimensional (1D) channels, 21 Å in width, running along the c axis, with a distance of 4.4 Å between the stacking 2D sheets. The porosity and specific surface area were determined using nitrogen adsorption isotherms at 77 K (Fig. 2C). The Brunauer-Emmett-Teller (BET) surface area was determined to be 1360 m²/g. Density functional theory (DFT) fitting of the adsorption branches showed relatively narrow pore size distributions (10 to 18 Å), in agreement with that of the proposed model.

For electrochemical experiments, the activated microcrystalline COF powders were deposited on porous, conductive carbon fabric. Cyclic voltammetry (CV) measurements on COF-366-Co were conducted in pH 7 aqueous phosphate buffer (Fig. 3A). Under a nitrogen atmosphere, the voltammogram trace shows a departure from the electrode background at about −0.46 V versus a reversible hydrogen electrode (RHE). A broad reduction wave, which was assigned to the Co(II)/Co(I) redox couple, is also apparent at about −0.67 V. The surface concentration of electrochemically active cobalt porphyrin sites was measured by integration of the reduction wave to be $1 \times 10^{-8}$ mol/cm², corresponding to activity at 4% of the cobalt porphyrin sites in the material. The observed continuous current increase at potentials more negative than −0.67 V likely arises from Co(I)-catalyzed proton reduction activity (39). After the solution was saturated with carbon dioxide, a substantial current enhancement was observed [catalytic current/ noncatalytic current ratio ($i_{cat}/i_p$) = 1.8 at −0.67 V (40), with a catalytic onset potential at −0.42 V, indicating a prominent catalytic effect of COF-366-Co on the reduction of carbon dioxide in neutral aqueous solution. In contrast, the carbon fabric electrode alone showed minimal current enhancement under a carbon dioxide or nitrogen atmosphere (fig. S56).

In controlled potential electrolyses performed in carbon dioxide–saturated aqueous bicarbonate buffer (pH = 7.3) under applied potentials between −0.57 and −0.97 V (versus RHE), carbon monoxide was observed as the major reduction product (Fig. 3B), with no other detectable carbon-based products. At −0.67 V, which represents an overpotential of −0.55 V, the catalyst displayed optimal performance (figs. S63 and S64). More positive potentials led to sluggish carbon dioxide reactivity, whereas more negative potentials promoted off-pathway water reduction. At −0.67 V, COF-366-Co promoted carbon monoxide evolution at an initial current density of 5 mA per milligram of catalyst (~80 mA per milligram of cobalt), with high selectivity over competing proton reduction [Faradaic efficiency for carbon monoxide (FE_{CO}) = 90%]. Catalytic cobalt porphyrin centers in the COF showed greater than 10% enhancement in carbon dioxide to proton selectivity over the molecular cobalt porphyrin unit alone (Fig. 3B). The catalytic activity of the COF could be maintained for 24 hours, accumulating more than 36 ml of carbon monoxide [standard

**Fig. 1. Design and synthesis of metalloporphyrin-derived 2D covalent organic frameworks.**

The space-filling structural models of COF-366-M and COF-367-M were obtained using Materials Studio 7.0 and refined with experimental PXRD data.
temperature and pressure (STP), equivalent to 1.6 mmol] per milligram of COF. This corresponds to a turnover number (TON) of 1352 [TON per electroactive cobalt based on the measurements described above (TON_{ex} = 34,000)], with an initial turnover frequency (TOF) of 98 hour$^{-1}$ [TOF per electroactive cobalt (TOF_{ex}) = 2500]. This result represents a substantial improvement over the molecular Co(TAP), which showed an initial TOF of 36 hour$^{-1}$ (TOF_{ex} = 380) and a TON of 794 (TON_{ex} = 8300) after 24 hours of reaction [surface coverage of electroactive sites on a Co(TAP)-modified electrode constitutes ~10% of the total cobalt]. PXRD (fig. S73) and SEM (fig. S74) measurements on the COF catalyst after electrolysis showed neither marked changes in crystallinity and microscopic morphology nor evidence of cobalt nanoparticle formation. By incorporating this molecular unit into a COF scaffold, the resulting hybrid catalyst could be recovered from the electrolysis mixture and reused at least five times without decrease in activity and selectivity (table S8). Control experiments with COFs containing either free-base or copper-metallated porphyrin units, a physical mixture of independently synthesized cobalt nanoparticles (fig. S75) and COF, and Co$_3$O$_4$ and related cobalt salts that could be formed as impurities during COF synthesis did not produce appreciable carbon dioxide reduction (fig. S76).

To optimize this carbon dioxide catalyst platform by a modular reticular approach, we prepared the expanded COF-367-Co analog using biphenyl-4,4'-dicarboxaldehyde (BPDA) as the strut in place of BDA (fig. 1). We reasoned that a larger pore size would allow for higher capacity of carbon dioxide adsorption inside the framework, as well as higher electrochemical and chemical accessibility of the catalytic cobalt porphyrin active sites. COF-367-Co was obtained as a dark purple powder comprising rectangular rod-shaped crystallite aggregates (~100 nm in length) (fig. 2D). The structural model based on PXRD data and DFT fitting indicated that the constitution and topology of COF-367-Co is analogous to that of COF-366-Co, with the former showing an increased channel width (24 Å) and interlayer distance (4.8 Å) (fig. 2E). The BET surface area was determined by nitrogen adsorption isotherm (fig. 2F) as 1470 m$^2$/g, and pore size distribution was consistent with the model (12 to 23 Å). Cyclic voltammetry studies with COF-367-Co on a carbon fabric electrode in bicarbonate buffer indicated that this extended organic framework exhibits an improved surface concentration ($2 \times 10^{-9}$ mol/cm$^2$) of electroactive cobalt porphyrin sites over COF-366-Co, which corresponds to accessibility of 8% of the cobalt sites in the bulk material. When the solution was saturated with CO$_2$, a catalytic current was evident with an onset potential at ~0.40 V and a 2.2-fold enhancement at ~0.67 V, indicating a prominent effect of COF-367-Co in the catalysis of CO$_2$ reduction at these potentials (fig. 3A). As predicted, electrolysis under the same conditions described above revealed that this expanded COF displays improved catalytic efficiency as compared with COF-366-Co. At an applied potential of ~0.67 V, COF-367-Co produced more than 100 ml of carbon monoxide (STP, equivalent to 4.5 mmol) per milligram of COF during a 24-hour period (TON = 3901, TON$_{ex}$ = 48,000), with high Faradaic efficiency (91%). The increased TON$_{ex}$ over COF-366-Co indicated that lattice expansion allowed for more efficient exposure of the electroactive sites to the reactants.

In addition to framework expansion, we also sought to optimize catalyst performance by introducing building-block heterogeneity through a multivariate strategy (33), as we hypothesized that not all electroactive cobalt porphyrin sites in the material fully participated in electrocatalysis, owing to the low aqueous solubility of carbon dioxide. Specifically, we reasoned that using isostructural metalloporphyrin units that are catalytically inactive for carbon dioxide reduction (fig. S76) to dilute electroactive cobalt porphyrin active sites within the extended lattice could increase the proportion of the active sites exposed to the reactant and thereby improve the turnover frequency on a per-cobalt basis. Copper porphyrin was chosen for this study, as the corresponding COF-367-Cu had the highest surface area among all analogous COF-367-M (M = Ni, Zn, H$_2$) synthesized. The resulting bimetallic COF-367 derivatives, termed COF-367-Co(10%) and COF-367-Co(3%), were prepared; the numbers in the parentheses indicate the proportion of cobalt in all metal sites (fig. 1). Inductively coupled plasma
ICP analyses confirmed that the final chemical composition of the COFs obtained reflected the initial ratio of the two metalloporphyrin starting materials that we used (supplementary materials section S1.1). The TOF per electroactive cobalt site for carbon monoxide production in these multivariate Co/Cu COF-367 catalysts showed a substantial improvement with each 10-fold dilution of cobalt loading. The average TOF per active cobalt for the first 4 hours of reaction was measured as follows: COF-367-Co, 165 hour$^{-1}$ (TOF$_{EA}$ ≈ 1900); COF-367-Co(10%), 380 hour$^{-1}$ (TOF$_{EA}$ ≈ 4400); and COF-367-Co(1%), 764 hour$^{-1}$ (TOF$_{EA}$ ≈ 9400) (Fig. 3C). The TOF$_{EA}$ values were roughly estimated, assuming that all three frameworks had comparable percentages of electroactive sites (8%). Although the low cobalt concentration in COF-367-Co(1%) and COF-367-Co(10%) hampered the accurate determination of the surface concentration of electrochemically accessible cobalt sites by CV, the bimetallic frameworks had nearly identical pore sizes, interlayer distances, and surface areas to the parent COF-367-Co on the basis of PXRD and nitrogen adsorption measurements (figs. S25 and S32 to S43), which suggests that such an assumption may be valid. Owing to the moderate

**Fig. 3.** Electrochemical and spectroelectrochemical characterizations and carbon dioxide reduction performance of the COFs. (A) Cyclic voltammograms of COF-366-Co and COF-367-Co in carbon dioxide–saturated medium (blue and red solid lines, respectively) or nitrogen-saturated medium (blue and red dotted lines, respectively). The black solid line shows background (bare carbon electrode) CV responses in carbon dioxide–saturated medium. The medium was pH 7.2 aqueous potassium phosphate buffer (0.2 M) with additives: 0.5 M KHCO$_3$ under carbon dioxide atmosphere to maintain a neutral pH, or 0.5 M NaClO$_4$ under nitrogen atmosphere to match the ionic strength. (B) Long-term bulk electrolyses at −0.67 V (versus RHE), showing the volume of carbon monoxide produced by COF-367-Co (red solid triangles), COF-366-Co (blue solid circles), or Co(TAP) (black solid squares) and the volume of hydrogen produced by COF-367-Co (red open triangles), COF-366-Co (blue open circles), or Co(TAP) (black open squares). (C) Bulk electrolyses of bimetallic COFs at −0.67 V (versus RHE), showing TON of carbon monoxide production by COF-367-Co(1%) (red solid triangles), COF-367-Co10% (blue solid circles), COF-367-Co (orange solid squares), or COF-367-Cu (purple solid inverted triangle); TON with respect to the amount of copper porphyrin. Two separate experimental runs were conducted for each time point, with the line showing the average of the measurements. (D) Long-term bulk electrolysis of COF-367-Co(1%) at −0.67 V (versus RHE). (E) Tafel plots of electrolysis using COF-367-Co (red solid circles), COF-366-Co (blue solid triangles), or Co(TAP) (black solid diamonds), showing only the linear, low–current density regime where the reaction rate is not limited by mass transport. (F) X-ray absorption spectra of COF-367-Co (orange line), COF-367-Co(10%) (blue line), and Co(TAP) (black line). The inset shows the pre-edge regime of the same spectra. (G) Spectroelectrochemical data using in situ UV-Vis, showing the steady-state relative absorbance at different applied potentials (0.23 to −0.57 V versus RHE) with reference to that at 0.33 V. (H) Time dependence of the relative UV-Vis absorbance at 640-nm wavelength at −0.57 V, with respect to the steady-state UV-Vis absorbance at 640 nm at 0.33 V. Potential is applied at 4 s. Linear regression yielded the apparent diffusion coefficient ($D_{app}$) according to a modified Cottrell equation: $\Delta\text{Absorption} = \frac{2A_{max}D_{app}/t^{1/2}}{d^{3/2}}$ (fig. S81) (47). Here, $A_{max}$ is the maximum absorption of the thin films at 640 nm, $d$ is the overall thickness of the thin films, and $t$ is time.
indeed, the analogous physical mixture of COF-
metallic COFs are due to their multivariate nature; 
observed activity enhancements for the bime-
UV-Vis spectrum of the FTO-supported COF 
bon dioxide 
electrochemistry. Under an applied potential 
Co thin films was characterized using spectro-
and 40% for COF-367-Co(1%). In a long-term 
charge-transport properties led to a higher cata-
rent conductivity of COF-366-Co to be ~10 
3G), and a fit of the data to a modified Cottrell 
ac c e n t e r w i t h a m o r e delocalized electronic 
structure, a network-solid analog to noninnocent 
catalysts showed a first-order rate dependence 
reduction by a different mechanism than that 
which pertains with the simple molecular an-
alog. In addition, both the COF and Co(TAP) 
catalysts showed a first-order rate dependence 
on the partial pressure of carbon dioxide (fig. 
S87) and no rate dependence on the pH (figs. 
S88 and S89), indicating that the rate-limiting chemi-
ical step involves the participation of one mole-
cule of carbon dioxide and no proton.

Finally, we applied x-ray absorption spectro-
copy (XAS) as a probe to evaluate how the sur-
rounding COF influenced the electronic structures 
of incorporated catalytic cobalt porphyrin units 
and, in turn, the associated carbon dioxide re-
duction mechanism (48, 49). Comparison of 
the cobalt K-edge XAS spectra of Co(TAP), COF-367-
and COF-367-Co(10%) (Fig. 3F) reveals a sim-
ilar line size, shape, and position, consistent with 
a formal Co(II) oxidation state for all samples. 
When a reduction potential (~0.67 V) was applied 
to COF-367-Co under a carbon dioxide atmo-
sphere, the K-edge revealed a line-shape change 
consistent with the partial reduction of Co(II) 
to Co(I) (fig. S96). The two COF catalysts also 
excerpt exhibited an additional pre-edge feature not 
present in the molecular Co(TAP) analog (Fig. 
3F, inset); this difference shows that the COF 
environment could directly modulate the elec-
tronic properties of molecular centers coupled 
into the extended lattice (50, 51). This feature, 
unique to the COFs, was also observed when COF 
catalysts were subjected to open-circuit or elec-
trolysis (~0.67 V) potentials in a bicarbonate 
buffer (figs. S92 to S95). The communication 
between the metal and COF lattice could furnish 
a carbon center with a more delocalized electronic 
structure, a network-solid analog to noninnocent 
ligand behavior in molecular systems (35).

Incorporating tunable molecular units with 
in an extended COF thus gives rise to electrocata-
lysts that display advantageous features of both 
molecular and heterogeneous systems and promote 
carbon dioxide reduction to carbon monoxide 
with exceptionally high activity and selectivity 
compared with existing systems (table S21). We

anticipate that these hybrid molecular–material platforms will be applicable to a broad range of catalytic applications, particularly those that 
require sustainable electrical and/or solar input and 
aqueous compatibility.

39. In pH 7.2 phosphate buffer, electrolysis at potentials equal to 
or more negative than ~0.67 V resulted in moderate hydrogen 
 evolution reaction. However, this activity was largely suppressed 
when the solution was saturated with carbon dioxide (see below).
40. The intrinsic i_{pa}/i_{pc} value was likely higher, as under carbon 
dioxide atmosphere, the current resulting from proton reduction 
was inhibited.
45. The COF-coated glassy carbon showed an ill-defined GIXAS 
pattern due to high background scattering (figs. S52 and S53).
Because the synthetic conditions were identical to those used 
with FTO and silicon oxide, we assumed that the COF 
grown on glassy carbon also formed a crystalline thin film.
46. E_{pa} could not be accurately measured with this method, 
owing to decomposition of FTO at potentials more negative than ~0.5 V.
251–258 (2012).
Subduction zone megathrust faults produce most of the world’s largest earthquakes. Although the physical properties of these faults are difficult to observe directly, their frictional strength can be estimated indirectly by constraining the orientations of the stresses that act on them. A global investigation of stress orientations in subduction zones finds that the maximum compressive stress axis plunges systematically trenchward, consistently making an angle of 45° to 60° with respect to the subduction megathrust fault. These angles indicate that the megathrust fault is not substantially weaker than its surroundings. Together with several other lines of evidence, this implies that subduction zone megathrusts are weak faults in a low-stress environment. The deforming outer accretionary wedge may decouple the stress state along the megathrust from the constraints of the free surface.

ubduction zones pose a considerable hazard as the main source of great earthquakes (magnitude ≥8). Relative to other fault types, subduction zone megathrust faults may also have unique physical properties, due to the sediments and fluids that are entrained by the subducting oceanic plate (1). The presence of fluids, particularly at high fluid pressures, can weaken faults substantially (2). Direct evidence suggests that subduction zone megathrust faults slip with low frictional resistance near Earth’s surface (3). The strength of these faults at seismogenic depths is less clear, as they can only be studied indirectly.

The orientation of a fault with respect to the stress field can be an indicator of the fault’s strength. Faults optimally oriented for frictional failure make an angle of 10° to the maximum compressive stress axis, σ1. Nonoptimally oriented faults can also be active, but faults with typical frictional strength should not slip at a high angle to σ1 (±60°) (4). Faults operating at a high angle to σ1 must be very weak compared to the surrounding material to slip at relatively low applied shear stress. Similarly, faults oriented at a very low angle to σ1 (<10°) must also be weak.

The traction at Earth’s surface is zero, requiring an Andersonian stress state in which one principal stress axis is vertical (5). Most crustal faulting is consistent with an Andersonian stress state (6). The very shallow dip (~10°) of the upper portion of many subduction zone megathrusts (7) suggests that, if these faults exist within an Andersonian stress state, they operate at a high angle to one principal stress axis (and at a low angle to the other two) and are therefore frictionally weak. However, observations from some subduction zone locations indicate that the stress in these locations is not Andersonian (8–11).

I systematically investigate the stress orientations in subduction zones worldwide, to determine whether the stress state is generally non-Andersonian and whether megathrust faults are well-oriented for failure. I compile the moment tensors (12, 13) of earthquakes located within 20 km of the subduction zone interface (7) to represent the megathrust region, and more shallow events to represent the upper plate. I stack the events for each subduction zone to invert for stress orientation (14) as a one-dimensional function of subduction interface depth. For the several subduction zones near Japan, there are enough moment tensors to invert for the two-dimensional spatially varying stress field as well.

The stress state in the subduction zones near Japan is generally not Andersonian. The σ1 axis in most megathrust regions plunges systematically trenchward (opposite the direction of subduction zone dip), generally plunging between 10° and 50° (Fig. 1A). A similar plunge of the σ1 axis is observed within the upper plate above the Japan Trench, Kuril Trench, and Nankai Trough (Fig. 1G), whereas back-arc extension (near-vertical σ1) dominates above the Ryukyu and Izu-Bonin trenches.

Comparing the plunge of the σ1 axis in the megathrust region to the dip of the subduction interface (7) gives the angle of σ1 to the megathrust fault (Fig. 1B). For the Kuril, Japan, and Izu-Bonin trenches, the σ1 axis is typically at an angle of 20° to 50° to the fault. For the Ryukyu Trench, the σ1 axis makes somewhat larger angles of 30° to 80° to the fault. In the Nankai Trough, σ1 is oriented at 10° to 30° to the fault in the upper 20 km, while at deeper depths, the σ1 axis is near-vertical. The plunge of the σ1 axis is stable with depth (Fig. 1C), except in the Nankai Trough (Fig. 1D), and the subduction megathrust is generally well oriented for failure from the near-surface to at least 60 km depth (Fig. 1E). The stacked Kuril, Japan, and Izu-Bonin trenches (the subducting Pacific plate) show a megathrust fault that is optimally oriented for failure, at ~30° to σ1 over the full depth range. The megathrust at the Ryukyu Trench is generally well oriented for failure at ~60° down to 30 km depth, and is marginally oriented at ~60° from 30 km to 60 km depth. The exception is the Nankai Trough (Fig. 1F), which is well oriented at ~20° to σ1 only in the upper 20 km. Below 30 km, the megathrust is not oriented for reverse faulting within the error bounds. This suggests that 30 km is the downward limit of coupling between the subducting and overriding plates.

For all global subduction zones studied, for almost all depths, the σ1 axis plunges systematically trenchward, with plunge generally between 10° and 50° (Fig. 2A). The plunge tends to decrease with depth, while the subduction zone dip increases (7), so that the angle of σ1 to the subduction interface is remarkably stable with depth (Fig. 2B). This angle is also remarkably similar across subduction zones, most falling within the range 45° to 60°.

The Japan and South American subduction zones are anomalous in being more optimally
